Abstract

This paper deals with finding outliers (exceptions) in large, multidimensional datasets. The identification of outliers can lead to the discovery of truly unexpected knowledge in areas such as electronic commerce, credit card fraud, and even the analysis of performance statistics of professional athletes. Existing methods that we have seen for finding outliers in large datasets can only deal efficiently with two dimensions/attributes of a dataset. Here, we study the notion of *DB*- (*Distance-Based*) outliers. While we provide formal and empirical evidence showing the usefulness of *DB*-outliers, we focus on the development of algorithms for computing such outliers.

First, we present two simple algorithms, both having a complexity of $O(k\,N^2)$, k being the dimensionality and N being the number of objects in the dataset. These algorithms readily support datasets with many more than two attributes. Second, we present an optimized cell-based algorithm that has a complexity that is linear wrt N, but exponential wrt k. Third, for datasets that are mainly disk-resident, we present another version of the cell-based algorithm that guarantees at most 3 passes over a dataset. We provide experimental results showing that these cell-based algorithms are by far the best for $k \leq 4$.

1 Introduction

Knowledge discovery tasks can be classified into four general categories: (a) dependency detection, (b) class identification, (c) class description, and (d) exception/outlier detection. The first three categories of tasks correspond to patterns that apply to many objects, or to a large percentage of objects, in the dataset. Most research in data mining (e.g., association rules [AIS93, MTV95, MT96], classification [AGI+92], data clustering [EKSX96, NH94, ZRL96], and concept generalization [HCC92, KN96]) belongs to these 3 categories. The fourth category, in contrast, focuses on a very small percentage of data objects, which are often ignored or discarded as noise. For example, some existing algorithms in machine learning and data mining have considered outliers, but only to the extent of tolerating them in whatever the algorithms are supposed to do [AL88, EKSX96, NH94, ZRL96].

"One person's noise is another person's signal." Indeed, for some applications, the rare events are often more interesting than the common ones, from a knowledge discovery standpoint. Sample applications include the detection of credit card fraud and the monitoring of criminal activities in electronic commerce [Kno97]. For example, in Internet commerce or smart card applications, we expect many low-value transactions to occur. However, it is the exceptional cases—exceptional perhaps in monetary amount, type of purchase, timeframe, location, or some combination thereof—that may interest us, either for fraud detection or for marketing reasons.

IBM's Advanced Scout data mining system has shown that data mining tools can be used to discover knowledge for strategic advantage in National Basketball Association games [BCP+97]. In Section 2.2, we give some concrete examples of detecting outliers in National Hockey League (NHL) data.

1.1 Related Work

Most of the existing work on outlier detection lies in the field of statistics [BL94, Haw80]. While there is no single, generally accepted, formal definition of an outlier, Hawkins' definition captures the spirit: "an outlier is an observation that deviates so much from other observations as to arouse suspicions that it was generated by a different mechanism" [Haw80]. Accordingly, over one hundred discordancy/outlier tests have been developed for different circumstances, depending on: (i) the data distribution, (ii) whether or not the distribution parameters (e.g., mean and variance) are known, (iii) the number of expected outliers, and even (iv) the types of expected outliers (e.g., upper or lower outliers in an ordered sample) [BL94]. However, those tests suffer from two serious problems. First, almost all of them are univariate (i.e., single attribute). This restriction makes them unsuitable for multidimensional datasets. Second, all of them are distribution-based. In numerous situations where we do not know whether a particular attribute follows a normal distribution, a gamma distribution, etc., we have to perform extensive testing to find a distribution that fits the attribute.

To improve the situation, some methods in computational statistics have been developed, which can be best described as depth-based. Based on some definition of depth, data objects are organized in layers in the data space, with the expectation that shallow layers are more likely to contain outlying data objects than the deep layers. *Peeling* and *depth contours* are two notions of depth studied in [PS88, RR96]. These depth-based methods avoid the problem of distribution fitting, and conceptually allow multidimensional data objects to be processed. However, in practice, the computation of k-dimensional layers relies on the computation of k-dimensional convex hulls. Because the lower bound complexity of computing a k-dimensional convex hull is $\Omega(N^{\lceil \frac{k}{2} \rceil})$, depth-based methods are not expected to be practical for more than 4 dimensions for large datasets. In fact, existing depth-based methods only give acceptable performance for $k \leq 2$ [RR96].

Arning, *et al.* [AAR96] search a dataset for implicit redundancies, and extract data objects called *sequential exceptions* that maximize the reduction in Kolmogorov complexity. This notion of outliers is very different from the aforementioned statistical definitions of outliers. As will be seen shortly, it is also very different from the notion of outliers considered here, primarily because there is not an associated notion of distance and similarity measure between objects.

Finally, a few clustering algorithms, such as CLARANS [NH94], DBSCAN [EKSX96] and BIRCH [ZRL96], are developed with exception-handling capabilities. However, their main objective is to find clusters in a dataset. As such, their notions of outliers are defined indirectly through the notion of clusters, and they are developed only to optimize clustering, but not to optimize outlier detection.

1.2 Distance-Based Outliers and Contributions of this Paper

The notion of outliers studied here is defined as follows:

An object O in a dataset T is a $DB(p, D)$-outlier if at least fraction p of the objects in T lies greater than distance D from O.

We use the term $DB(p, D)$-outlier as shorthand notation for a *D*istance-*B*ased outlier (detected using parameters p and D). This intuitive notion of outliers is consistent with Hawkins' definition. It is suitable for situations where the observed distribution does not fit any standard distribution. More importantly, it is well-defined for k-dimensional datasets for any value of k. Unlike the depth-based methods, DB-outliers are not restricted computationally to small values of k. While depth-based methods rely on the computation of layers in the data space, DB-outliers go beyond the data space and rely on the computation of distance values based on a metric distance function.[1]

We do not claim that DB-outliers can replace all existing notions of outliers and can be used universally. Indeed, depth-based outliers would be more applicable than DB-outliers to situations where no reasonable metric distance function can be used. However, for numerous applications that are not readily supported by existing methods, defining a distance function is not hard. Our work builds on the premise that knowledge discovery is best facilitated by keeping a human user involved. The choice of p and D, and validity checking (i.e., deciding whether each $DB(p, D)$-outlier is a "real" outlier of any significance), is left to a human expert.[2]

The specific parts and contributions of this paper are as follows:

- We show that the notion of distance-based outliers generalizes the notions of outliers supported by statistical outlier tests for standard distributions. Because this material appears in our preliminary work [KN97], Section 2.1 only provides a brief summary. Algorithms, optimizations, and disk-residency were not the focus of our previous work, but are the focus here.

- We present two simple algorithms in Section 3 having a complexity of $O(k\,N^2)$, where k and N are the dimensionality and size of the dataset, respectively. The detection of DB-outliers, unlike the depth-based approaches, is computationally tractable for values of $k > 2$.

[1] Algorithms presented here assume that the distance function is (weighted) Euclidean.

[2] The values of p and D do provide indications on how "strong" an identified outlier is. Many existing approaches for finding outliers, including the depth-based approaches, do not provide such indications.

- We present a partitioning-based algorithm in Section 4 that, for a given dimensionality k, has a complexity of $O(N)$. The algorithm, however, is exponential on k. We show that, in some cases, this algorithm outperforms the two simple algorithms by at least an order of magnitude for $k \leq 4$.
- We present a different version of the partitioning-based algorithm in Section 5 for large, disk-resident datasets. We show that the algorithm guarantees at most 3 passes over the dataset. Again, experimental results indicate that this algorithm is by far the best for $k \leq 4$.

2 Justification for DB-Outliers

In this section, we provide two justifications for finding DB-outliers. The first is formal, and the second is empirical. In Section 2.1, we show how DB-outliers generalize certain statistical outlier tests. In Section 2.2, we show a few sample runs of our DB-outlier detection package using actual NHL data.

2.1 Properties of $DB(p, D)$-Outliers

Definition 1 $DB(p, D)$ *unifies*[3] or *generalizes* another definition *Def* for outliers, if there exist specific values p_0, D_0 such that: object O is an outlier according to *Def* iff O is a $DB(p_0, D_0)$-outlier. □

For a normal distribution, outliers can be considered to be observations that lie 3 or more standard deviations (i.e., $\geq 3\sigma$) from the mean μ [FPP78].

Definition 2 Define Def_{Normal} as follows: t is an outlier in a normal distribution with mean μ and standard deviation σ iff $|\frac{t-\mu}{\sigma}| \geq 3$. □

Lemma 1 $DB(p, D)$ unifies Def_{Normal} with $p_0 = 0.9988$ and $D_0 = 0.13\sigma$, that is, t is an outlier according to Def_{Normal} iff t is a $DB(0.9988, 0.13\sigma)$-outlier.

Proofs of the lemmas in this section have already been documented [KN97]. Note that if the value 3σ in Def_{Normal} is changed to some other value, such as 4σ, the above lemma can easily be modified with the corresponding p_0 and D_0 to show that $DB(p, D)$ still unifies the new definition of Def_{Normal}. The same general approach applies to a Student t-distribution, which has fatter tails than a normal distribution. The principle of using a tail to identify outliers can also be applied to a Poisson distribution.

Definition 3 Define $Def_{Poisson}$ as follows: t is an outlier in a Poisson distribution with parameter $\mu = 3.0$ iff $t \geq 8$. □

Lemma 2 $DB(p, D)$ unifies $Def_{Poisson}$ with $p_0 = 0.9892$ and $D_0 = 1$. □

[3] DB-outliers are called *unified* outliers in our preliminary work [KN97].

Finally, for a class of regression models, we can define an outlier criterion $Def_{Regression}$, and show that $DB(p, D)$ unifies $Def_{Regression}$ [KN97].

2.2 Sample Runs Using NHL Statistics

During in-lab experiments on historical NHL data, we have identified outliers among players having perhaps "ordinary looking" statistics which suddenly stand out as being non-ordinary when combined with other attributes. Portions of sample runs of these experiments are documented in Figure 1.

The first example shows that, in 1994, Wayne Gretzky and Sergei Fedorov were outliers when 3 attributes—points scored, plus-minus statistic,[4] and number of penalty minutes—were used. Fedorov was an outlier because his point and plus-minus figures were much higher than those of almost all other players. (As a reference note, the "average" NHL player has fewer than 20 points, a plus-minus statistic of 0, and fewer than 100 penalty minutes.) Gretzky was an outlier because of his high point total and low plus-minus figure. In fact, we were surprised that Gretzky's plus-minus figure was so poor, especially since he was the highest scorer in the league that year, and since high scorers usually have positive plus-minus values (as confirmed by Fedorov in the same example).[5] Using the same 3 attributes for 1996 data (see the second example), we note that Vladimir Konstantinov had an astonishingly high plus-minus statistic (i.e., +60) despite having a rather mediocre point total.

Our third example shows that Chris Osgood and Mario Lemieux were outliers when 3 attributes—games played, goals scored, and shooting percentage (i.e., goals scored, divided by shots taken)—were used. Few NHL players had shooting percentages much beyond 20%, but Osgood's shooting percentage really stood out. Despite playing 50 games, he only took 1 shot, on which he scored. Osgood's outlier status is explained by the fact that he is a goalie, and that goalies have rarely scored in the history of the NHL. Lemieux was an outlier, not because he scored on 20.4% of his shots, but because no other player in the 20% shooting range had anywhere near the same number of goals and games played.

Whereas the above 3 examples contain outliers that are extreme in some dimension, the 4th example is different. None of Alexander Mogilny's statistics was extreme in any of the 5 dimensions. The NHL range

[4] The plus-minus statistic indicates how many more even-strength goals were scored by the player's team—as opposed to the opposition's team—when this particular player was on the ice. For example, a plus-minus statistic of +2 indicates that this player was on the ice for 2 more goals scored *by* his team than *against* his team.

[5] The next highest scorer in negative double digits did not occur until the 23rd position overall. Perhaps Gretzky's plus-minus can be explained by the fact that he played for the Los Angeles Kings that year—a team not known for its strong defensive play.

```

Figure 1: Sample Output Involving NHL Players' Statistics

for each of the 5 attributes (with Mogilny's statistic in parentheses) was as follows: 1–84 games played (79), 0–31 power play goals (10), 0–8 shorthanded goals (5), 0–12 game winning goals (6), and 0–4 game tieing goals (3). In contrast, 3 of 5 statistics for Mario Lemieux were extreme.

In all of these examples, a user chose suitable values for p and D to define the "strength" of the outliers requested. These values depend on the attributes being analyzed and each attribute's distribution. The quest for suitable values for p and D may involve trial and error and numerous iterations; therefore, in future work, we will use sampling techniques to estimate a suitable starting value for D, given some value of p close to unity (e.g., $p = 0.999$). We also plan on supporting user-defined distance functions (including statistical distance functions which account for variability among attributes [JW92]).

3 Simple Algorithms for Finding All $DB(p, D)$-Outliers

3.1 Index-Based Algorithms

Let N be the number of objects in dataset T, and let F be the underlying distance function that gives the distance between any pair of objects in T. For an object O, the D-neighbourhood of O contains the set of objects $Q \in T$ that are within distance D of O (i.e., $\{Q \in T \mid F(O,Q) \leq D\}$). The fraction p is the minimum fraction of objects in T that must be *outside* the D-neighbourhood of an outlier. For simplicity of discussion, let M be the maximum number of objects within the D-neighbourhood of an outlier, i.e., $M = N(1-p)$.

From the formulation above, it is obvious that given p and D, the problem of finding all $DB(p, D)$-outliers can be solved by answering a nearest neighbour or range query centred at each object O. More specifically, based on a standard multidimensional indexing structure, we execute a range search with radius D for each object O. As soon as $(M+1)$ neighbours are found in the D-neighbourhood, the search stops, and O is declared a non-outlier; otherwise, O is an outlier.

Analyses of multidimensional indexing schemes [HKP97] reveal that, for variants of R-trees [Gut84] and k-d trees [Ben75, Sam90], the lower bound complexity for a range search is $\Omega(N^{1-1/k})$, where k is the number of dimensions or attributes and N is the number of data objects. As k increases, a range search quickly reduces to $O(N)$, giving at best a constant time improvement reflecting sequential search. Thus, the above procedure for finding all $DB(p, D)$-outliers has a worst case complexity of $O(k\,N^2)$. Two points are worth noting:

- Compared to the depth-based approaches, which have a lower bound complexity of $\Omega(N^{\lceil \frac{k}{2} \rceil})$, DB-outliers scale much better with dimensionality. The framework of DB-outliers is applicable and computationally feasible for datasets that have many attributes, i.e., $k \geq 5$. This is a significant improvement on the current state-of-the-art, where existing methods can only realistically deal with two attributes [RR96].
- The above analysis only considers search time. When it comes to using an index-based algorithm, most often for the kinds of data mining applications under consideration, it is a very strong assumption that the right index exists. As will be shown in Section 6, the index building cost alone, even without counting the search cost, almost always renders the index-based algorithms uncompetitive.

3.2 A Nested-Loop Algorithm

To avoid the cost of building an index for finding all $DB(p, D)$-outliers, Algorithm NL shown in Figure 3.2 uses a block-oriented, nested-loop design. Assuming a total buffer size of $B\%$ of the dataset size, the algorithm divides the entire buffer space into two halves,

called the *first* and *second* arrays. It reads the dataset into the arrays, and directly computes the distance between each pair of objects or tuples.[6] For each object t in the first array, a count of its D-neighbours is maintained. Counting stops for a particular tuple whenever the number of D-neighbours exceeds M.

Algorithm NL

1. Fill the first array (of size $\frac{B}{2}$% of the dataset) with a block of tuples from T.
2. For each tuple t_i in the first array, do:
   a. $count_i \leftarrow 0$
   b. For each tuple t_j in the first array, if $\text{dist}(t_i, t_j) \leq D$:
      Increment $count_i$ by 1. If $count_i > M$, mark t_i as a non-outlier and proceed to next t_i.
3. While blocks remain to be compared to the first array, do:
   a. Fill the second array with another block (but save a block which has never served as the first array, for last).
   b. For each unmarked tuple t_i in the first array do:
      For each tuple t_j in the second array, if $\text{dist}(t_i, t_j) \leq D$:
      Increment $count_i$ by 1. If $count_i > M$, mark t_i as a non-outlier and proceed to next t_i.
4. For each unmarked tuple t_i in the first array, report t_i as an outlier.
5. If the second array has served as the first array anytime before, stop; otherwise, swap the names of the first and second arrays and goto step 2.

Figure 2: Pseudo-Code for Algorithm NL

As an example, consider Algorithm NL with 50% buffering, and denote the 4 logical blocks of the dataset by A, B, C, D, with each block/array containing $\frac{1}{4}$ of the dataset. Let us follow the algorithm, filling the arrays in the following order, and comparing:

1. A with A, then with B, C, D—for a total of 4 block reads;
2. D with D (no read required), then with A (no read), B, C—for a total of 2 block reads;
3. C with C, then with D, A, B—for a total of 2 blocks reads; and
4. B with B, then with C, A, D—for a total of 2 block reads.

Thus, in this example, a grand total of 10 blocks are read, amounting to $\frac{10}{4} = 2.5$ passes over the entire dataset. Later, in Section 5.3, we compute the number of passes required in the general case.

Algorithm NL avoids the explicit construction of any indexing structure, and its complexity is $O(kN^2)$. Compared to a tuple-by-tuple brute force algorithm that pays no attention to I/O's, Algorithm NL is superior because it tries to minimize I/O's.

[6]From here on in, we use the terms *object* and *tuple* interchangeably.

In the following two sections, we present two versions of a cell-based algorithm that has a complexity linear with respect to N, but exponential with respect to k. This algorithm is therefore intended only for small values of k. The key idea is to gain efficiency by using cell-by-cell processing instead of tuple-by-tuple processing, thereby avoiding the N^2 complexity term.

4 A Cell-Based Approach

Let us begin with a *simplified* version of the algorithm, which assumes that both the multidimensional cell structure and the entire dataset fit into main memory. For ease of presentation, we begin with 2-D, and then proceed to k-D. In Section 5, we give the full version of the algorithm for handling disk-resident datasets.

4.1 Cell Structure and Properties in 2-D

Suppose our data objects are 2-D. We quantize each of the data objects into a 2-D space that has been partitioned into cells or squares of length $l = \frac{D}{2\sqrt{2}}$. Let $C_{x,y}$ denote the cell that is at the intersection of row x and column y. The Layer 1 (L_1) neighbours of $C_{x,y}$ are the immediately neighbouring cells of $C_{x,y}$, defined in the usual sense, that is,

$$L_1(C_{x,y}) = \{C_{u,v} \mid u = x \pm 1,\ v = y \pm 1,\ C_{u,v} \neq C_{x,y}\}. \quad (1)$$

A typical cell (except for any cell on the boundary of the cell structure) has 8 L_1 neighbours.

Property 1 Any pair of objects within the same cell is at most distance $\frac{D}{2}$ apart. □

Property 2 If $C_{u,v}$ is an L_1 neighbour of $C_{x,y}$, then any object $P \in C_{u,v}$ and any object $Q \in C_{x,y}$ are at most distance D apart. □

Property 1 is valid because the length of a cell's diagonal is $\sqrt{2}l = \sqrt{2}\frac{D}{2\sqrt{2}} = \frac{D}{2}$. Property 2 is valid because the distance between any pair of objects in the two cells cannot exceed twice the length of a cell's diagonal. We will see that these two properties are useful in ruling out many objects as outlier candidates. The Layer 2 (L_2) neighbours of $C_{x,y}$ are those additional cells within 3 cells of $C_{x,y}$, i.e.,

$$L_2(C_{x,y}) = \{C_{u,v} \mid u = x \pm 3,\ v = y \pm 3,\ C_{u,v} \notin L_1(C_{x,y}),\ C_{u,v} \neq C_{x,y}\}. \quad (2)$$

A typical cell (except for any cell on or near a boundary) has $7^2 - 3^2 = 40$ L_2 cells. Note that Layer 1 is 1 cell thick and Layer 2 is 2 cells thick. L_2 was chosen in this way to satisfy the following property.

Property 3 If $C_{u,v} \neq C_{x,y}$ is neither an L_1 nor an L_2 neighbour of $C_{x,y}$, then any object $P \in C_{u,v}$ and any object $Q \in C_{x,y}$ must be $>$ distance D apart. □

Since the combined thickness of L_1 and L_2 is 3 cells, the distance between P and Q must exceed $3l = \frac{3D}{2\sqrt{2}} > D$.

Property 4 (a) If there are $> M$ objects in $C_{x,y}$, *none* of the objects in $C_{x,y}$ is an outlier.

(b) If there are $> M$ objects in $C_{x,y} \cup L_1(C_{x,y})$, *none* of the objects in $C_{x,y}$ is an outlier.

(c) If there are $\leq M$ objects in $C_{x,y} \cup L_1(C_{x,y}) \cup L_2(C_{x,y})$, *every* object in $C_{x,y}$ is an outlier. □

Properties 4(a) and 4(b) are direct consequences of Properties 1 and 2, and 4(c) is due to Property 3.

4.2 Algorithm FindAllOutsM for Memory-Resident Datasets

Figure 3 presents Algorithm FindAllOutsM to detect all $DB(p, D)$-outliers in memory-resident datasets. Later, in Section 5.2, we present an enhanced algorithm to handle disk-resident datasets.

Algorithm FindAllOutsM

1. For $q \leftarrow 1, 2, \dots m$, $\quad Count_q \leftarrow 0$
2. For each object P, map P to an appropriate cell C_q, store P, and increment $Count_q$ by 1.
3. For $q \leftarrow 1, 2, \dots, m$, $\quad$ if $Count_q > M$, label C_q *red*.
4. For each *red* cell C_r, label each of the L_1 neighbours of C_r *pink*, provided the neighbour has not already been labelled *red*.
5. For each non-empty *white* (i.e., uncoloured) cell C_w, do:
   a. $Count_{w2} \leftarrow Count_w + \sum_{i \in L_1(C_w)} Count_i$
   b. If $Count_{w2} > M$, label C_w *pink*.
   c. else
      1. $Count_{w3} \leftarrow Count_{w2} + \sum_{i \in L_2(C_w)} Count_i$
      2. If $Count_{w3} \leq M$, mark all objects in C_w as outliers.
      3. else for each object $P \in C_w$, do:
         i. $Count_P \leftarrow Count_{w2}$
         ii. For each object $Q \in L_2(C_w)$, if $dist(P, Q) \leq D$:
            Increment $Count_P$ by 1. If $Count_P > M$, P cannot be an outlier, so goto 5(c)(3).
         iii. Mark P as an outlier.

Figure 3: Pseudo-Code for Algorithm FindAllOutsM

Step 2 of Algorithm FindAllOutsM quantizes each tuple to its appropriate cell. Step 3 labels all cells containing $> M$ tuples, *red*. This corresponds to Property 4(a). Cells that are L_1 neighbours of a *red* cell are labelled *pink* in step 4, and cannot contain outliers because of Property 4(b). Other cells satisfying Property 4(b) are labelled *pink* in step 5(b). Finally, in step 5(c)(2) of the algorithm, cells satisfying Property 4(c) are identified.

All of the properties mentioned in Section 4.1 are used to help determine outliers and non-outliers on a cell-by-cell basis, rather than on an object-by-object basis. This helps to reduce execution time significantly because we quickly rule out a large number of objects that cannot be outliers. For cells not satisfying any of Properties 4(a)-(c), we resort to object-by-object processing. Such cells are denoted as *white* cells (C_w). In step 5(c)(3) of Algorithm FindAllOutsM, each object $P \in C_w$ must be compared with every object Q lying in a cell that is an L_2 neighbour of C_w in order to determine how many Q's are inside the D-neighbourhood of P. As soon as the number of D-neighbours exceeds M, P is declared a non-outlier. If, after examining all Q's, the count remains $\leq M$, then P is an outlier.

4.3 Complexity Analysis: The 2-D Case

Let us analyze the complexity of Algorithm FindAllOutsM for the 2-D case. Step 1 takes $O(m)$ time, where $m \ll N$ is the total number of cells. Steps 2 and 3 take $O(N)$ and $O(m)$ time respectively. Since $M + 1$ is the minimum number of objects that can appear in a red cell, there are at most $\frac{N}{M+1}$ *red* cells. Thus, step 4 takes $O(\frac{N}{M+1})$ time. The time complexity of step 5 is the most complicated. In the worst case, (i) no cell is labelled *red* or *pink* in the previous steps, and (ii) step 5(c) is necessary for all cells. If no cell is coloured, then each cell contains at most M objects. Thus, in step 5(c), each of the objects in a cell can require the checking of up to M objects in each of the 40 L_2 neighbours of the cell; therefore, $O(40M^2)$ time is required for each cell. Hence, step 5 takes $O(mM^2)$ time. Since, by definition, $M = N(1 - p)$, we equate $O(mM^2)$ to $O(mN^2(1 - p)^2)$. In practice, we expect p to be extremely close to 1, especially for large datasets, so $O(mN^2(1-p)^2)$ can be approximated by $O(m)$. Thus, the time complexity of Algorithm FindAllOutsM in 2-D is $O(m+N)$. Note that this complexity figure is very conservative because, in practice, we expect many *red* and *pink* cells. As soon as this happens, there are fewer object-to-object comparisons. Thus, step 5(c) becomes less dominant, and the algorithm requires less time. In Section 6.2, we show experimental results on the efficiency of Algorithm FindAllOutsM.

4.4 Generalization to Higher Dimensions

When moving from $k = 2$ dimensions to $k > 2$, Algorithm FindAllOutsM requires only one change to incorporate a general k-D cell structure. That change involves the cell length l. Recall that in 2-D, $l = \frac{D}{2\sqrt{2}}$. Since the length of a diagonal of a k-D hypercube/cell of length l is $\sqrt{k}l$, the length l in a k-D setting must be changed to $\frac{D}{2\sqrt{k}}$ to preserve Properties 1 and 2.

Although the following comments do not change Algorithm FindAllOutsM, an understanding of which

cells appear in Layer 2 is important in correctly applying the algorithm. First, we note that the L_1 neighbours of cell $C_{x_1,\ldots,x_k}$ are:

$$L_1(C_{x_1,\ldots,x_k}) = \{C_{u_1,\ldots,u_k} \mid u_i = x_i \pm 1 \quad \forall 1 \leq i \leq k,\ C_{u_1,\ldots,u_k} \neq C_{x_1,\ldots,x_k}\} \quad (3)$$

which generalizes the definition given in (1). However, to preserve Property 3, the definition of L_2 neighbours needs to be modified. Specifically, since $l = \frac{D}{2\sqrt{k}}$, Layer 2 needs to be thicker than it is for $k = 2$. Let x denote the thickness of Layer 2. Then, the combined thickness of Layers 1 and 2 is $x + 1$. So, for Property 3 to hold, we require that $(x + 1)l > D$; consequently, we pick x as $\lceil 2\sqrt{k} - 1 \rceil$. The L_2 neighbours of $C_{x_1,\ldots,x_k}$ are therefore:

$$L_2(C_{x_1,\ldots,x_k}) = \{C_{u_1,\ldots,u_k} \mid u_i = x_i \pm \lceil 2\sqrt{k} \rceil \quad \forall\, 1 \leq i \leq k,\ C_{u_1,\ldots,u_k} \notin L_1(C_{x_1,\ldots,x_k}),\ C_{u_1,\ldots,u_k} \neq C_{x_1,\ldots,x_k}\} \quad (4)$$

which generalizes (2). In this way, Properties 1 to 4 listed in Section 4.1 are preserved.

4.5 Complexity Analysis: The Case for Higher Dimensions

For $k > 2$, the complexities of steps 1 to 4 in Algorithm FindAllOutsM remain the same. However, we note that m is exponential with respect to k, and may not necessarily be much less than N. Also, the complexity of step 5 is no longer $O(m)$, but $O(m(2\lceil 2\sqrt{k} \rceil + 1)^k) \approx O(c^k)$, where c is some constant depending on $\sqrt{k}$ and on $m^{1/k}$ (which roughly corresponds to the number of cells along each dimension). Thus, the complexity of the entire algorithm is $O(c^k + N)$.

While this complexity figure represents a worst case scenario, the question to ask is how efficient Algorithm FindAllOutsM is in practice for the general k-D case. We defer the answer to Section 6.4, but make the following preliminary comments. First, for the identification of "strong" outliers, the number of outliers to be found is intended to be small. This is achieved by having a relatively large value of D, and a value of p very close to unity. A large value of D corresponds to a small number of cells along each dimension. Thus, the constant c is small, but it is > 1. Second, for values of p very close to unity, M is small, implying that there will be numerous *red* and *pink* cells. This means that the savings realized by skipping *red* and *pink* cells is enormous, and that the number of objects requiring pairwise comparisons is relatively small.

5 *DB*-Outliers in Large, Disk-Resident Datasets

In the last section, we presented a cell-based algorithm that was simplified for memory-resident datasets. Here, we extend the simplified version to handle disk-resident datasets. This new version preserves the property of being linear with respect to N. It also provides the guarantee that no more than 3, if not 2, passes over the dataset are required.

5.1 Handling Large, Disk-Resident Datasets: An Example

In handling a large, disk-resident dataset, the goal is to minimize the number of page reads or passes over the dataset. In the cell-based algorithm, there are two places where page reads are needed:

- the *initial mapping* phase
  In step 2 of Algorithm FindAllOutsM, each object is mapped to an appropriate cell. This unavoidable step requires one pass over the dataset.
- the *object-pairwise* phase
  In step 5(c)(3), for each object P in a *white* cell C_w, each object Q in a cell that is an L_2 neighbour of C_w needs to be read to perform the object-by-object distance calculation. Since objects mapped to the same cell, or to nearby cells, are not necessarily physically clustered on disk, each pair of objects (P, Q) may require a page to be read, thereby causing a large number of I/O's. The point here is that if object-by-object distance calculations are to be done exactly as described in step 5(c)(3), then a page may be read many times.

The above scenario is an extreme case whereby no tuples/pages are stored in main memory. A natural question to ask is if, in the object-pairwise phase, it is possible to read each page only once. Let $Page(C)$ denote the set of pages that store at least one tuple mapped to cell C. Then, for a particular *white* cell C_w, we need to read the pages in $Page(C_w)$. Because we also need the tuples mapped to a cell C_v that is an L_2 neighbour of C_w (i.e., $C_v \in L_2(C_w)$), we need the pages in $Page(L_2(C_w)) = \bigcup_{C_v \in L_2(C_w)} Page(C_v)$. Also, if we want to ensure that pages in $Page(L_2(C_w))$ are only read once, we need to read the pages: (i) that are needed by C_v, because C_v itself may be a *white* cell, and (ii) that use C_v, because C_v may be an L_2 neighbour of yet another *white* cell. In general, the "transitive closure" of this page cascading may include every page in the dataset. Hence, the only way to ensure that a page is read at most once in the object-pairwise phase is to use a buffer the size of the dataset, which is clearly a strong assumption for large datasets.

Our approach is a "middle ground" scenario whereby only a selected subset of tuples is kept in main memory. This subset is the set of all tuples mapped to *white* cells. Hereinafter, we refer to such tuples as *white tuples*. This is our choice partly because these are the very tuples that need object-by-object calculations, and partly because the number of tuples in a

white cell, by definition, is bounded above by M. Furthermore, we classify all pages into three categories:

A. Pages that contain some *white* tuple(s)

B. Pages that do not contain any *white* tuple, but contain tuple(s) mapped to a *non-white* cell which is an L_2 neighbour of some white cell

C. All other pages

To minimize page reads, our algorithm first reads Class A pages, and then Class B pages. Following this, it suffices to re-read Class A pages to complete the object-pairwise phase. Class C pages are not needed here.

Consider a simple example where there are 600 pages in a dataset. Suppose pages 1 to 200 are Class A pages, pages 201 to 400 are Class B pages, and pages 401 to 600 are Class C pages. Suppose tuple P is mapped to *white* cell C_w, and is stored in (Class A) page i. For P to complete its object-by-object distance calculations, these three kinds of tuples are needed:

- *white* tuples Q mapped to a *white* L_2 neighbour of C_w
- *non-white* tuples Q mapped to a *non-white* L_2 neighbour of C_w, and stored in page $j \geq i$
- *non-white* tuples Q mapped to a *non-white* L_2 neighbour of C_w, but stored in page $j < i$

For the first kind of tuple, the pair (P, Q) is kept in main memory after the first 200 pages have been read, because both tuples are *white*. Thus, their separation can be computed and the appropriate counters (i.e., both P's and Q's) may be updated after all Class A pages have been read. For the second kind of tuple, the distance between the pair (P, Q) can be processed when page j is read into main memory, because P is already in main memory by then since $i \leq j$. The fact that Q is not kept around afterwards does not affect P at all. Thus, after the first 400 pages have been read (i.e., all class A and B pages), the second kind of tuples for P have been checked. The only problem concerns the third kind of tuples. In this case, when Q (which is stored in page j) is in main memory, P (which is stored in page $i > j$) has not been read. Since Q is a *non-white* tuple and is not kept around, then when P eventually becomes available, Q is gone. To deal with this situation, page j needs to be re-read. In general, all Class A pages (except one) may need to be re-read. But it should be clear that because all *white* tuples are kept in main memory, it is sufficient to read Class A pages a second time.

Before presenting the formal algorithm, we offer two generalizations to the above example. First, the example assumes that all Class A pages precede all Class B pages in page numbering, and that pages are read in ascending order. Our argument above applies equally well if these assumptions are not made—so long as all Class A pages are read first, followed by all Class B pages, and the necessary (re-reading of) Class A pages. Second, Class A pages can be further divided into two subclasses: (A.1) pages that do not store any *non-white* tuple that is needed, and (A.2) pages that store some *non-white* tuple(s) that are needed. If this subdivision is made, it should be obvious from the above analysis that in re-reading all Class A pages, it suffices to re-read only the Class A.2 pages. For simplicity, this optimization is not described in the algorithm below.

5.2 Algorithm FindAllOutsD for Disk-Resident Datasets

Figure 4 presents Algorithm FindAllOutsD for mining outliers in large, disk-resident datasets. Much of the processing in the first 5 steps of Algorithm FindAllOutsD is similar to that described for Algorithm FindAllOutsM shown in Figure 3. We draw attention to step 2 of Algorithm FindAllOutsD, which no longer stores P but makes a note of the fact that P's page contains some tuple(s) mapped to C_q. This is important because (i) we may need to access a given cell's tuples later in the algorithm, and (ii) we need to know which cells have tuples from a particular page.

Step 5(c)(2) colours a *white* cell *yellow* if it has been determined that every tuple in a given cell is an outlier. Its tuples will be identified in step 8 after they have been read from their pages in step 6. Step 6 reads only those pages containing at least one *white* or *yellow* tuple. With respect to Section 5.1, this corresponds to reading all Class A pages. The *white* and *yellow* tuples from these pages are stored with the cell C_w to which they have been quantized. C_w stores exactly $Count_w$ tuples, and this count is $\leq M$. To prepare for L_2 processing, step 6(b)(1)(ii) initializes the D-neighbour counter to the number of tuples in $C_w \cup L_1(C_w)$.

In step 7, for each non-empty *white* cell C_w, we determine how many more D-neighbours each tuple $P \in C_w$ has, using (as potential neighbours) just the tuples read and stored in step 6. As soon as we find that P has $> M$ D-neighbours, we mark P as a non-outlier. After step 7, it is possible that some (or all) of the non-empty *white* cells need no further comparisons, thereby reducing the number of reads in step 9.

Necessary disk reads for cells that are both *non-white* and *non-yellow* are performed in step 9. With respect to Section 5.1, this corresponds to reading all Class B pages, and re-reading (some) Class A pages. Again, we determine how many more D-neighbours that each tuple P in each *white* cell has, using only the newly read tuples from disk. If P has $> M$ D-neighbours, then P is marked as a non-outlier, and no further comparisons involving P are necessary.

Algorithm FindAllOutsD

1. For $q \leftarrow 1, 2, \ldots m, \quad Count_q \leftarrow 0$
2. For each object P in the dataset, do:
   a. Map P to its appropriate cell C_q but do not store P.
   b. Increment $Count_q$ by 1.
   c. Note that C_q references P's page.
3. For $q \leftarrow 1, 2, \ldots, m, \quad$ if $Count_q > M$, label C_q *red*.
4. For each *red* cell C_r, label each of the L_1 neighbours of C_r *pink*, provided the neighbour has not already been labelled *red*.
5. For each non-empty *white* (i.e., uncoloured) cell C_w, do:
   a. $Count_{w2} \leftarrow Count_w + \sum_{i \in L_1(C_w)} Count_i$
   b. If $Count_{w2} > M$, label C_w *pink*.
   c. else
      1. $Count_{w3} \leftarrow Count_{w2} + \sum_{i \in L_2(C_w)} Count_i$
      2. If $Count_{w3} \leq M$, label C_w *yellow* to indicate that all tuples mapping to C_w are outliers.
      3. else $Sum_w \leftarrow Count_{w2}$
6. For each page i containing at least 1 *white* or *yellow* tuple, do:
   a. Read page i.
   b. For each *white* or *yellow* cell C_q having tuples in page i, do:
      1. For each object P in page i mapped to C_q, do:
         i. Store P in C_q.
         ii. $Kount_P \leftarrow Sum_q$
7. For each object P in each non-empty *white* cell C_w, do:
   a. For each *white* or *yellow* cell $C_L \in L_2(C_w)$, do:
      1. For each object $Q \in C_L$, if $dist(P,Q) \leq D$:
         Increment $Kount_P$ by 1. If $Kount_P > M$, mark P as a non-outlier, and goto next P.
8. For each object Q in each *yellow* cell, report Q as an outlier.
9. For each page i containing at least 1 tuple that (i) is both *non-white* and *non-yellow*, and (ii) maps to an L_2 neighbour of some white cell C, do:
   a. Read page i.
   b. For each cell $C_q \in L_2(C)$ that is both *non-white* and *non-yellow*, and has tuples in page i, do:
      1. For each object Q in page i mapped to C_q, do:
         i. For each non-empty *white* cell $C_w \in L_2(C_q)$, do:
            For each object $P \in C_w$, if $dist(P,Q) \leq D$:
               Increment $Kount_P$ by 1. If $Kount_P > M$, mark P as a non-outlier.
10. For each object P in each non-empty *white* cell, if P has not been marked as a non-outlier, then report P as an outlier.

Figure 4: Pseudo-Code for Algorithm FindAllOutsD

5.3 Analysis of Algorithm FindAllOutsD and Comparison with Algorithm NL

Algorithm FindAllOutsD has a linear complexity wrt N for the same reasons explained for Algorithm FindAllOutsM (cf: Section 4.3), but by design, Algorithm FindAllOutsD has the following important advantage over Algorithm FindAllOutsM wrt I/O performance.

Lemma 3 Algorithm FindAllOutsD requires at most 3 passes over the dataset.

Proof Outline: The initial mapping phase requires one pass over the dataset. Let n be the total number of pages in the dataset. Then if n_1, n_2, n_3 denote the number of pages in Classes A, B, and C respectively (cf: Section 5.1), it is necessary that $n = n_1 + n_2 + n_3$. As shown in Section 5.1, the maximum total number of pages read in the object-pairwise phase is given by $n_1 + n_2 + n_1$, which is obviously $\leq 2n$. Thus, the entire algorithm requires no more than 3 passes. □

The above guarantee is conservative for two reasons. First, the sum $n_1 + n_2 + n_1$ can be smaller than n. For example, if $n_1 \leq n_3$, then the sum is $\leq n$, implying that while some page may be read 3 times, the total number of pages read is equivalent to no more than 2 passes over the dataset. Second, the above guarantee assumes that: (i) there is enough buffer space for storing the *white* tuples (as will be shown later, this is not a strong assumption because typically there are not too many non-empty *white* cells), and (ii) there is only one page remaining in the buffer space for Class A and B pages. More buffer space can be dedicated to keep more Class A pages around, thereby reducing the number of page re-reads for Class A pages.

At this point, let us revisit Algorithm NL, used for block-oriented, nested-loop processing of disk-resident datasets (cf: Section 3.2). We will show that Algorithm FindAllOutsD guarantees fewer dataset passes than Algorithm NL does, for sufficiently large datasets.

Lemma 4 If a dataset is divided into $n = \lceil \frac{200}{B} \rceil$ blocks (B is the percentage of buffering), then (i) the total number of block reads required by Algorithm NL is $n + (n-2)(n-1)$, and (ii) the number of passes over the dataset is $\geq n - 2$.

Proof Outline: (i) Each of the n blocks must be read exactly once during the first dataset pass. At the end of each pass, we retain 2 blocks in memory, so only $n-2$ additional blocks need to be read during passes 2, 3, ..., n. Thus, $n + (n-2)(n-1)$ blocks are read. (ii) The number of dataset passes is: $\frac{n+(n-2)(n-1)}{n} = \frac{n^2-2n+2}{n} = n - 2 + \frac{2}{n} \geq n - 2$. □

In general, Algorithm NL may require many more passes than Algorithm FindAllOutsD. For example, if a large dataset is split into $n = 10$ pieces, Lemma 4 states that Algorithm NL requires $n - 2 = 10 - 2 = 8$ passes, which is 5 more passes than Algorithm FindAllOutsD may need.

6 Empirical Behaviour of the Algorithms

6.1 Experimental Setup

Our base dataset is an 855-record dataset consisting of 1995-96 NHL player performance statistics. These statistics include numbers of goals, assists, points, penalty minutes, shots on goal, games played, power play goals, etc. Since this real-life dataset is quite small, and since we want to test our algorithms on large, disk-resident datasets, we created a number of synthetic datasets mirroring the distribution of statistics within the NHL dataset. More specifically, we determined the distribution of the attributes in the original dataset by using 10-partition histograms. Then, we generated datasets containing between 10,000 and 2,000,000 tuples, whose distributions mirrored that of the base dataset. Each page held up to 13 tuples.

All of our tests were run on a Sun Microsystems UltraSPARC-1 machine having 128 MB of main memory. Unless otherwise indicated, all times shown in this paper are CPU times plus I/O times.[7] Our code was written in C++ and was processed by an optimizing compiler. The modes of operation that we used, and their acronyms, are as follows:

1. CS is a multidimensional cell structure implementation as described by either Algorithm FindAllOutsM or FindAllOutsD. The context makes it clear which algorithm is being evaluated.

2. NL is an implementation of Algorithm NL. The amount of memory permitted for buffering in each NL case is the same amount of memory required by CS. For example, if CS uses 10 MB of main memory, then 10 MB is also available for NL.

3. KD is a memory-based k-d tree implementation.

4. RT is a disk-based R-tree implementation.

Range query processing in KD and RT modes has been optimized to terminate as soon as the number of D-neighbours exceeds M.

6.2 Varying the Dataset Size

Figure 5 shows results for various modes and various dataset sizes for 3-D, using $p = 0.9999$. Specifically, it shows how CPU + I/O time is affected by the number of tuples. (The x-axis is measured in millions of tuples.) For example, CS takes 256.00 seconds in total time to find all the appropriate DB-outliers in a 2 million tuple dataset. In contrast, NL takes 2332.10 seconds, about 9 times as long. RT mode is even less

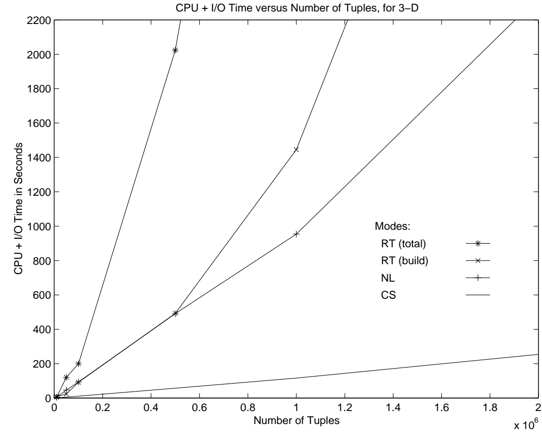

Figure 5: How CPU + I/O Time Scales with N for 3-D Disk-Resident Datasets, Using $p = 0.9999$

Table 1: CPU Times (in Seconds) for 3-D, Memory-Resident Datasets, using $p = 0.9995$

N	CS	NL	KD
20000	0.32	1.02	3.14
40000	0.54	4.26	20.49
60000	0.74	9.64	33.08
80000	1.04	17.58	54.66
100000	1.43	27.67	104.28

competitive. Unlike CS, RT is not linear wrt N. In fact, just building the R-tree can take at least 10 times as long as CS, let alone searching the tree.

While the preceding paragraph concerns disk-resident datasets, Table 1 summarizes the results for *memory-resident* datasets in 3-D, using $p = 0.9995$. Again, CS can outperform NL by an order of magnitude, and the index-based algorithm—a k-d tree (KD) in this case—takes much longer, even if we just consider the time it takes to build the index.

6.3 Varying the Value of p

Figure 6 shows how the percentages of *white*, *pink*, *red*, and non-empty *white* cells vary with p.[8] The total number of cells is simply the sum of the *red, pink,* and *white* cells. Processing time is less when there is a greater percentage of *red* and *pink* cells because we can quickly eliminate a larger number of tuples from being considered as outliers. The success of the cell-based algorithms is largely due to the fact that many of the cells may be *red* or *pink* (and there may be relatively few non-empty *white* cells). Recall that non-empty

[7] Our CPU timer wraps around after 2147 seconds; hence, times beyond this are unreliable. Where we have quoted a CPU + I/O figure > 2147, it is because the CPU time was < 2147, but the I/O time actually caused the sum to exceed 2147. (CPU time and I/O time were measured separately.)

[8] We include *yellow* cells with the *white* cell population since *yellow* cells are just a special type of *white* cell.

white cells require the most computational effort.

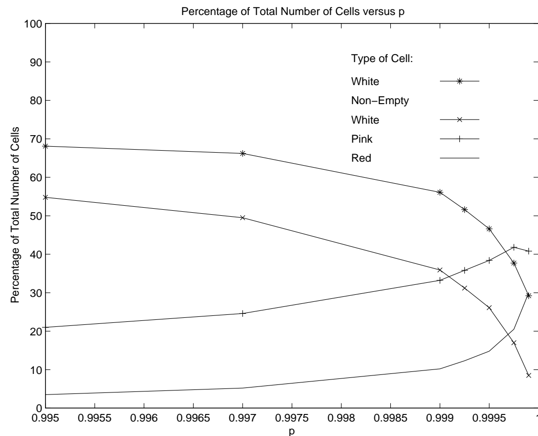

Figure 6: 3-D Cell Colouring Statistics for Variable p, for 500,000 Tuples

6.4 Varying the Number of Dimensions and Cells

In this section, we see how the number of dimensions and cells affects performance. We omit the trivial 1-D and 2-D results, but show results for 3-D, 4-D, and 5-D. Beyond 5-D, we believe that NL will be the clear winner. Table 2 shows how CS and NL compare in different dimensions for disk-resident datasets of various sizes, using $p = 0.9999$.

For CS mode in 5-D, we varied the number of partitions m_i in a given dimension i. We chose $m_i = 10$, 8, and 6 for each dimension. The columns CS(10^5), CS(8^5), and CS(6^5) stand for cases where the cell structure contains $m = \Pi_{i=1}^{k} m_i = 10^5$, 8^5, and 6^5 cells, respectively. The table shows that (i) CS outperforms NL in 3-D by almost an order of magnitude, (ii) CS clearly outperforms NL in 4-D, and (iii) NL is the clear winner in 5-D. Due to the exponential growth in the number of cells, CS is uncompetitive with NL in 5-D.

Even when the number of cells is greatly reduced in 5-D, CS generally cannot beat NL. In fact, of all the 5-D tests we ran (in addition to those shown in Table 2), there was only one case where CS actually beat NL. Perhaps surprisingly, the table shows that a reduction in the number of cells in 5-D does not necessarily result in a reduction in total time. This is due to an I/O optimization that we included in our implementation, whereby dramatic savings are achieved for larger numbers of cells (for values of p close to unity).[9] Without the optimization, however, it is true that reducing the number of cells normally results in a reduction in total time. Our implementation uses a hybrid strategy whereby we turn off the optimization at certain thresholds of p and m.

Finally, because we made CS and NL use the same amount of memory for fair comparison, the amount of buffer space available to NL increased as k increased. This explains why the execution time of NL shown in Table 2 often dropped with increasing dimensions.

7 Conclusions

We believe that identifying DB-outliers is an important and useful data mining activity. In this paper, we proposed and analyzed several algorithms for finding DB-outliers. In addition to two simple $O(k\,N^2)$ algorithms, we developed cell-based algorithms that are linear with respect to N and are suitable for $k \leq 4$. The cell-based algorithm developed for large, disk-resident datasets also guarantees that no data page is read more than 3 times, if not once or twice. Our empirical results suggest that (i) the cell-based algorithms are far superior to the other algorithms for $k \leq 4$ (in some cases, by at least an order of magnitude), (ii) the nested-loop algorithm is the choice for $k \geq 5$ dimensions, and (iii) finding all DB-outliers is computationally very feasible for large, multidimensional datasets (e.g., 2.5 minutes total time for 500,000 tuples in 5-D). Using Algorithm NL, there is no practical limit on the size of the dataset or on the number of dimensions.

In ongoing work, we are developing incremental techniques that allow the user to freely experiment with p and D, but do not require the cell structure to be recomputed from scratch for every change of the parameters. We are also looking for ways to incorporate user-defined distance functions, and to provide incremental support for changing distance functions.

[9] In particular, for a non-empty white cell C_w, as soon as the number of D-neighbours exceeds M for all of C_w's tuples, we explicitly search through $L_2(C_w)$'s cells looking for red or pink cells. For each such red or pink cell, we determine the block ID's (pages) that contain tuples mapped to it, and then we subtract 1 from the respective block ID counters. Later in the program, when it comes time to read the block, if the block ID counter is no longer positive, we avoid reading and processing the page because we know that this page is no longer needed. Thus, for the additional expense of searching $L_2(C_w)$ cells, we may realize substantial savings; however, this advantage is lost as p becomes smaller or as the overall number of cells becomes fewer.
